1 Deterministic Case

Consider the following reinforcement learning problem.

s_1	s_2	s_3	s_4
s_5	s_6	s_7	s_8
s_9	s_{10}	s_{11}	s_{12}

- There are 12 states, and the actions are $\{up, down, left, right\}$. Legal actions are those that go to the immediate neighbor, horizontally or vertically (but not diagonally). State s_7 is the goal state, and the only action here is to itself with reward 0. Treat State 7 (s_7) as having no legal action.
- The rewards for all action are 0, except for all actions that lead into s_7 , which are 100.
- In all cases, assume $\gamma = 0.9$.

Problem 1 (Program: 20 pts): Program a Q-learning algorithm to learn the $Q(s, a)$ values for the above example. Use the algorithm in slide04.pdf, Mitchell slide page 18 (pdf page 22). Stop learning when change in the Q table is 0 for the past 50 Q updates or so. Note: use a random policy to select action a given current state s (take care to check if the random action chosen is a legal one).

(1) Include your code.

(2) Show resulting Q table (12×4 matrix).

- Rows represent state and columns represent action.
- Row ordering should be s_1, s_2, \dots, s_9 .
- Column ordering should be $up, down, left, right$, from left to right. **If you use a different ordering you will get 0 points for this problem.**
- Set $Q(s, a) = -99$ to mark illegal moves. Don't use this value during your calculations.

(3) Show a plot showing $\sum_{s,a} |Q_{t+1}(s, a) - Q_t(s, a)|$ over the iterations t .

Problem 2 (Program: 20 pts): Modify the program from problem 1 so that the exploration policy is ϵ -greedy. Initialize your Q table with a very small random number to break the initial tie ($\text{rand} * 0.0001$).

(1) Include your code.

(2) Test $\epsilon \in \{0.0, 0.2, 0.5, 1.0\}$. Note: $\epsilon = 1.0$ is the greedy policy, and $\epsilon = 0.0$ is the random policy.

If $\text{rand}() > \text{epsilon}$, choose random action. Otherwise, choose $[\text{val}, a] = \max(Q(s, :))$.

(3) Show resulting Q tables for all 4 cases (9×4 matrix).

(4) Show plots showing $\sum_{s,a} |Q_{t+1}(s, a) - Q_t(s, a)|$ over the iterations t for all four cases.

(5) Discuss the effect of ϵ on the quality of the learned Q-table.

2 Stochastic Case

Consider a stochastic version of the reinforcement learning problem posed in Section 1. Modify the rules so that:

- $\delta(s, a)$ is stochastic: The probability of landing in the intended direction is 0.70. The probability of landing in one of n unintended legal direction is $\frac{0.30}{n}$.
- Example 1 : If you are in s_5 and a was right, probability of landing in s_6 is 0.70, and ending up in s_1 or s_9 is 0.15 each.
- Example 2: If you are in s_1 and a was down, probability of landing in s_5 is 0.70, and ending up in s_2 is 0.30.
- Reward $r(s, a)$ depends on where you landed based on the above. All rewards are 0 unless the resulting state was the goal state s_7 . For example, if you were in s_6 and the action was $a = \text{left}$, with 10% chance you will land in s_7 , the goal state. In this case $r(s_6, \text{left}) = 100$ for that specific run. In a different run, if you landed in s_1 , then $r(s_6, \text{left}) = 0$.

Problem 3 (Program: 20 pts): Repeat problem 1, with the stochastic version of the task (random policy). In addition to all the requirements, keep a running estimate of $E[r(s, a)]$ for states s_3, s_6, s_8 , and s_{11} and report their **final** values. Use the learning rule in slide04.pdf, Mitchell slide page 31 (pdf page 35).

Estimating $E[r(s, a)]$ throughout the learning run:

$$E[r(s, a)] = \frac{\sum_{\forall \text{ visits to } (s, a)} \text{observed reward } r}{\text{visits}(s, a)}$$

Problem 4 (Program: 20 pts): Repeat problem 2, with the stochastic version of the task (ϵ -greedy policy with the four different ϵ values). In addition to all the requirements, keep a running estimate of $E[r(s, a)]$ for states s_3, s_6, s_8 , and s_{11} and report the values. Use the learning rule in slide04.pdf, Mitchell slide page 31 (pdf page 35).

Problem 5 (Written: 10 pts): For states s_3, s_6, s_8 , and s_{11} manually compute $E[r(s, a)]$ (using the exact probabilities [note: it relates with $P(s'|s, a)$ and the reward depending on state outcome s']) and compare those to the estimated values from problem 3 and problem 4. Are the results similar?

Problem 6 (Written: 10 pts): For states s_3 , s_6 , s_8 , and s_{11} , using the estimated $E[r(s, a)]$ and all the estimated $\hat{Q}(s, a)$ values from your simulation result in problem 3 above, see if the following holds:

$$\hat{Q}(s, a) = E[r(s, a)] + \gamma \sum_{s'} P(s'|s, a) \max_{a'} \hat{Q}(s', a')$$
