Lecture 5: Dimensionality reduction (PCA)

The curse of dimensionality

Dimensionality reduction

- Feature selection Vs. feature extraction
- Signal representation Vs. classification

Principal Components Analysis

The curse of dimensionality (1)

• The curse of dimensionality

- A term coined by Bellman in 1961
- Refers to the problems associated with multivariate data analysis as the dimensionality increases
- We will illustrate these problems with a simple example

Consider a 3-class pattern recognition problem

- A simple approach would be to
 - Divide the feature space into uniform bins
 - Compute the ratio of examples for each class at each bin and,
 - For a new example, find its bin and choose the predominant class in that bin
- In our toy problem we decide to start with one single feature and divide the real line into 3 segments

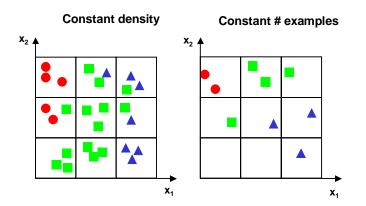

• After we have done this, we notice that there exists too much overlap for the classes, so we decide to incorporate a second feature to try and improve the classification rate

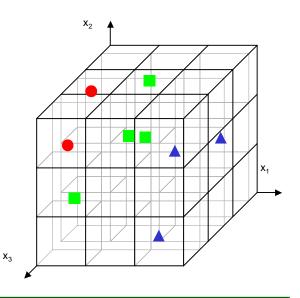

The curse of dimensionality (2)

- We decide to preserve the granularity of each axis, which raises the number of bins from 3 (in 1D) to 3²=9 (in 2D)
 - At this point we are faced with a decision: do we maintain the density of examples per bin or do we keep the number of examples we used for the one-dimensional case?
 - Choosing to maintain the density increases the number of examples from 9 (in 1D) to 27 (in 2D)
 - Choosing to maintain the number of examples results in a 2D scatter plot that is very sparse

Moving to three features makes the problem worse:

- The number of bins grows to 3³=27
- For the same density of examples the number of needed examples becomes 81
- For the same number of examples, well, the 3D scatter plot is almost empty

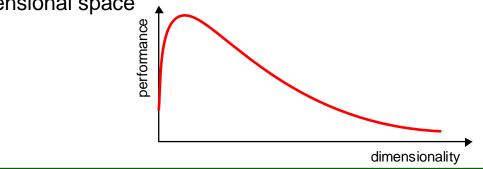

The curse of dimensionality (3)

- Of course, our approach to divide the sample space into equally spaced bins was quite inefficient
 - There are other approaches that are much less susceptible to the curse of dimensionality, **but the problem still exists**

How do we beat the curse of dimensionality?

- By incorporating prior knowledge
- By providing increasing smoothness of the target function
- By reducing the dimensionality
- In practice, the curse of dimensionality means that, for a given sample size, there is a maximum number of features above which the performance of our classifier will degrade rather than improve
 - In most cases, the additional information that is lost by discarding some features is (more than) compensated by a more accurate mapping in the lowerdimensional space

The curse of dimensionality (4)

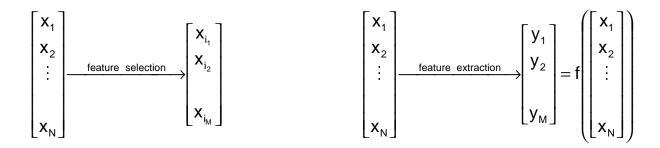

There are many implications of the curse of dimensionality

- Exponential growth in the number of examples required to maintain a given sampling density
 - For a density of N examples/bin and D dimensions, the total number of examples is N^D
- Exponential growth in the complexity of the target function (a density estimate) with increasing dimensionality
 - "A function defined in high-dimensional space is likely to be much more complex than a function defined in a lower-dimensional space, and those complications are harder to discern" --Friedman
 - This means that a more complex target function requires denser sample points to learn it well!
- What to do if it ain't Gaussian?
 - For one dimension, a large number of density functions can be found in textbooks, but for high-dimensions almost only the multivariate Gaussian density is left, and for larger values of D, the Gaussian density can only be handled in a simplified form!
- Humans have an extraordinary capacity to discern patterns and clusters in 1, 2 and 3-dimensions, but these capabilities degrade drastically for 4 or higher dimensions

Dimensionality reduction (1)

- Two approaches are available to perform dimensionality reduction
 - Feature extraction: creating a subset of new features by combinations of the existing features
 - Feature selection: choosing a subset of all the features (the ones more informative)
 - Feature selection will be covered at the end of the course

The problem of feature extraction can be stated as

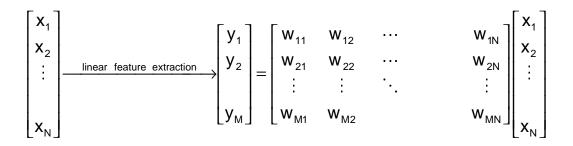

- Given a feature space x_i∈ R^N find a mapping y=f(x):R^N→R^M with M<N such that the transformed feature vector y_i∈ R^M preserves (most of) the information or structure in R^N.
- An optimal mapping y=f(x) will be one that results in no increase in the minimum probability of error
 - This is, the probability of error is the same when a Bayes decision rule is applied on initial space R^N and in the reduced space R^M

Dimensionality reduction (2)

In general, the optimal mapping y=f(x) will be a non-linear function

- However, there is no systematic way to generate non-linear transforms
 - The selection of a particular subset of transforms is problem dependent
- For this reason, feature extraction is commonly limited to linear transforms: **y=Wx**
 - This is, *y* is a linear projection of *x*
 - NOTE: When the mapping is a non-linear function, the reduced space is called a **manifold**

 We will focus on linear feature extraction for now on, and revisit non-linear techniques when we cover multi-layer perceptrons

Signal representation versus classification

- The selection of the feature extraction mapping y=f(x) is guided by an objective function that we seek to maximize (or minimize)
- Depending on the criteria measured by the objective function, feature extraction techniques are grouped into two categories:
 - **Signal representation**: The goal of the feature extraction mapping is to represent the samples accurately in a lower-dimensional space
 - **Classification**: The goal of the feature extraction mapping is to enhance the class-discriminatory information in the lower-dimensional space
- Within the realm of linear feature extraction, two techniques are commonly used
 2
 - Principal Components Analysis (PCA)
 - uses a signal representation criterion
 - Linear Discriminant Analysis (LDA)
 - uses a classification criterion

Principal Components Analysis, PCA (1)

- The objective of PCA is to perform dimensionality reduction while preserving as much of the randomness in the high-dimensional space as possible
 - Let x be an N-dimensional random vector, represented as a linear combination of orthonormal basis vectors $[\phi_1 | \phi_2 | \dots | \phi_N]$ as

$$x = \sum_{i=1}^{N} y_i \phi_i \text{ where } \phi_i \mid \phi_j = \begin{cases} 0 & i \neq j \\ 1 & i = j \end{cases}$$

 Suppose we choose to represent x with only M (M<N) of the basis vectors. We can do this by replacing the components [y_{M+1}, ..., y_N]^T with some pre-selected constants

$$\hat{x}(M) = \sum_{i=1}^{M} y_i \phi_i + \sum_{i=M+1}^{N} b_i \phi_i$$

• The representation error is then

$$\Delta \mathbf{x}(\mathbf{M}) = \mathbf{x} - \hat{\mathbf{x}}(\mathbf{M}) = \sum_{i=1}^{N} \mathbf{y}_i \boldsymbol{\phi}_i - \left(\sum_{i=1}^{M} \mathbf{y}_i \boldsymbol{\phi}_i - \sum_{i=M+1}^{N} \mathbf{b}_i \boldsymbol{\phi}_i\right) = \sum_{i=M+1}^{M} (\mathbf{y}_i - \mathbf{b}_i) \boldsymbol{\phi}_i$$

• We choose to measure this representation error by the mean-squared magnitude of Δx

$$\overline{\epsilon}^{2}(M) = \mathsf{E}\Big[\!\left|\Delta x(M)\right|^{2}\Big] = \mathsf{E}\!\left[\sum_{i=M+1}^{N}\sum_{j=M+1}^{N} (y_{i} - b_{i})(y_{j} - b_{j})\phi_{i}^{\mathsf{T}}\phi_{j}\right] = \sum_{i=M+1}^{N} \mathsf{E}\!\left[\!(y_{i} - b_{i})^{2}\right]$$

 Among all the basis vectors \$\u03c6 i\$ and constants bi we choose the ones that minimize this mean-square error

Principal Components Analysis, PCA (2)

• The optimal values of b_i are found by computing the partial derivative of the objective function and equating to zero

$$\frac{\partial}{\partial b_i} E[(y_i - b_i)^2] = -2(E[y_i] - b_i) = 0 \implies b_i = E[y_i]$$

- So we will replace the discarded y_i's by their expected value (an intuitive solution)
- The mean-square error can be written as

$$\begin{split} \overline{\epsilon}^2(\mathsf{M}) &= \sum_{i=\mathsf{M}+1}^{\mathsf{N}} \mathsf{E}\Big[\big(\mathsf{y}_i - \mathsf{E}[\mathsf{y}_i] \big)^2 \Big] = \sum_{i=\mathsf{M}+1}^{\mathsf{N}} \mathsf{E}\Big[\big(\mathsf{x} \boldsymbol{\phi}_i - \mathsf{E}[\mathsf{x} \boldsymbol{\phi}_i] \big)^T \big(\mathsf{x} \boldsymbol{\phi}_i - \mathsf{E}[\mathsf{x} \boldsymbol{\phi}_i] \big) \Big] \\ &= \sum_{i=\mathsf{M}+1}^{\mathsf{N}} \boldsymbol{\phi}_i^\mathsf{T} \mathsf{E}\Big[\big(\mathsf{x} - \mathsf{E}[\mathsf{x}] \big) \big(\mathsf{x} - \mathsf{E}[\mathsf{x}] \big)^T \Big] \boldsymbol{\phi}_i = \sum_{i=\mathsf{M}+1}^{\mathsf{N}} \boldsymbol{\phi}_i^\mathsf{T} \boldsymbol{\Sigma}_{\mathsf{x}} \boldsymbol{\phi}_i \end{split}$$

• We seek to find the solution that minimizes this expression subject to the orthonormality constraint, which we incorporate into the expression using a set of Lagrange multipliers λ_i

$$\overline{\epsilon}^{2}(M) = \sum_{i=M+1}^{N} \boldsymbol{\phi}_{i}^{\mathsf{T}} \boldsymbol{\Sigma}_{x} \boldsymbol{\phi}_{i} + \sum_{i=M+1}^{N} \lambda_{i} (1 - \boldsymbol{\phi}_{i}^{\mathsf{T}} \boldsymbol{\phi}_{i})$$

• Computing the partial derivative with respect to the basis vectors

$$\frac{\partial}{\partial \phi_{i}} \overline{\epsilon}^{2}(M) = \frac{\partial}{\partial \phi_{i}} \left[\sum_{i=M+1}^{N} \phi_{i}^{T} \Sigma_{x} \phi_{i} + \sum_{i=M+1}^{N} \lambda_{i} (1 - \phi_{i}^{T} \phi_{i}) \right] = 2 \left(\Sigma_{x} \phi_{i} - \lambda_{i} \phi_{i} \right) = 0 \implies \Sigma_{x} \phi_{i} = \lambda_{i} \phi_{i}$$

$$NOTE: \frac{d}{dx} \left(x^{T} A x \right) = \left(A + A^{T} \right) x^{\text{if } A \text{ is }}_{x} = 2Ax$$

• So ϕ_i and λ_i are the eigenvectors and eigenvalues of the covariance matrix Σ_x

Principal Components Analysis, PCA (3)

• We can express the sum-square error as

$$\overline{\epsilon}^{2}(M) = \sum_{i=M+1}^{N} \phi_{i}^{\mathsf{T}} \Sigma_{\mathsf{x}} \phi_{i} = \sum_{i=M+1}^{N} \phi_{i}^{\mathsf{T}} \lambda_{i} \phi_{i} = \sum_{i=M+1}^{N} \lambda_{i}$$

- In order to minimize this measure, λ_i will have to be smallest eigenvalues
 - Therefore, to represent x with minimum sum-square error, we will choose the eigenvectors φ_i corresponding to the largest eigenvalues λ_i

PCA dimensionality reduction

The optimal* approximation of a random vector $x \in \Re^N$ by a linear combination of M (M<N) independent vectors is obtained by projecting the random vector x onto the eigenvectors φ_i corresponding to the largest eigenvalues λ_i of the covariance matrix Σ_x

*optimality is defined as the minimum of the sum-square magnitude of the approximation error

Principal Components Analysis, PCA (4)

NOTES

- Since PCA uses the eigenvectors of the covariance matrix Σ_x , it is able to find the independent axes of the data under the unimodal Gaussian assumption
 - For non-Gaussian or multi-modal Gaussian data, PCA simply de-correlates the axes
- The main limitation of PCA is that it does not consider class separability since it does not take into account the class label of the feature vector
 - PCA simply performs a coordinate rotation that aligns the transformed axes with the directions of maximum variance
 - There is no guarantee that the directions of maximum variance will contain good features for discrimination!!!

Historical remarks

- Principal Components Analysis is the oldest technique in multivariate analysis
- PCA is also known as the Karhunen-Loève transform (communication theory)
- PCA was first introduced by Pearson in 1901, and it experienced several modifications until it was generalized by Loève in 1963

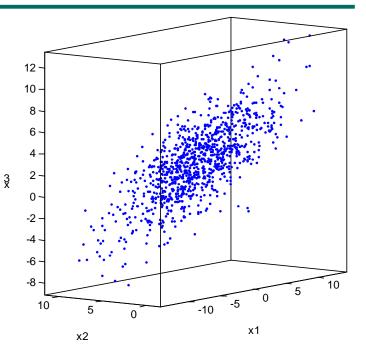

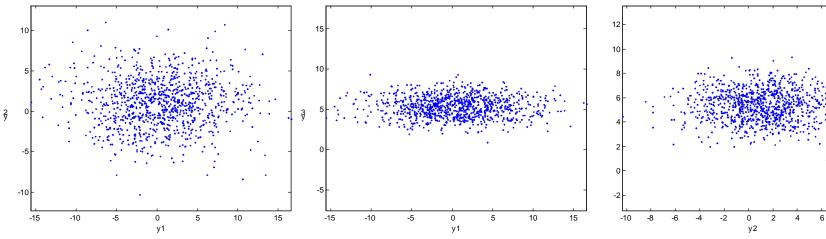

PCA examples (1)

 In this example we have a three-dimensional Gaussian distribution with the following parameters

$$\boldsymbol{\mu} = \begin{bmatrix} 0 \ 5 \ 2 \end{bmatrix}^{\mathsf{T}} \text{ and } \boldsymbol{\Sigma} = \begin{bmatrix} 25 & -1 & 7 \\ -1 & 4 & -4 \\ 7 & -4 & 10 \end{bmatrix}$$

- The three pairs of principal component projections are shown below
 - Notice that the first projection has the largest variance, followed by the second projection
 - Also notice that the PCA projections de-correlate the axis (we knew this since Lecture 2)

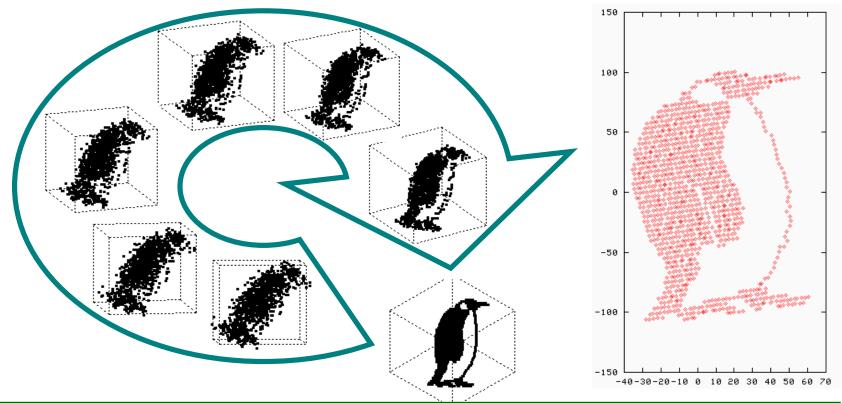

Introduction to Pattern Recognition Ricardo Gutierrez-Osuna Wright State University

PCA examples (2)

- This example shows a projection of a three-dimensional data set into two dimensions
 - Initially, except for the elongation of the cloud, there is no apparent structure in the set of points
 - Choosing an appropriate rotation allows us to unveil the underlying structure. (You can think of this rotation as "walking around" the three-dimensional set, looking for the best viewpoint)
- PCA can help find such underlying structure. It selects a rotation such that most of the variability within the data set is represented in the first few dimensions of the rotated data
 - In our three-dimensional case, this may seem of little use
 - However, when the data is highly multidimensional (10's of dimensions), the analysis is quite powerful
